Higher-level data

Lists

Tuples

Pattern Matching

Data in Haskell

- ▶ Data has a different Type

Data in Haskell

- ▶ Data has a different Type
- ▶ Int and Char are the most common.

Data in Haskell

- ▶ Data has a different Type
- ▶ Int and Char are the most common.
- ▶ Data can be abstracted into Tuples and lists

Data in Haskell

- ▶ Data has a different Type
- ▶ Int and Char are the most common.
- ▶ Data can be abstracted into Tuples and lists
- ▶ Typeclasses are interfaces for similar data.

Working with lists

- ▶ Lists collect data of the same type.

Working with lists

- ▶ Lists collect data of the same type.
- ▶ Comprehensions allow you to filter lists to your liking.

Working with lists

- ▶ Lists collect data of the same type.
- ▶ Comprehensions allow you to filter lists to your liking.
- ▶ Mapping over lists returns a list of data with a function applied to it.

Working with lists

- ▶ Lists collect data of the same type.
- ▶ Comprehensions allow you to filter lists to your liking.
- ▶ Mapping over lists returns a list of data with a function applied to it.
- ▶ The notation `[Type]` creates a list. `[Bool]` is a list of booleans.

Working with Tuples

- ▶ Tuples “types” are determined by the number of elements they have, and what types are in what location.
- ▶ (Int,Char) is a valid tuple.

Pattern matching

- ▶ Any data can be pattern matched.

Pattern matching

- ▶ Any data can be pattern matched.
- ▶ Asks “Does the data look like this?”

Pattern matching

- ▶ Any data can be pattern matched.
- ▶ Asks “Does the data look like this?”
- ▶ The list `[1,2]` is syntax sugar for `1:2`

Pattern matching

- ▶ Any data can be pattern matched.
- ▶ Asks “Does the data look like this?”
- ▶ The list `[1,2]` is syntax sugar for `1:2`
- ▶ The pattern `(x:xs:[])` matches `1` is then bound to `x`, `2` to `c`, and they are indeed appended to an empty list, so the match completes.

Pattern matching

- ▶ Any data can be pattern matched.
- ▶ Asks “Does the data look like this?”
- ▶ The list `[1,2]` is syntax sugar for `1:2`
- ▶ The pattern `(x:xs:[])` matches `1` is then bound to `x`, `2` to `c`, and they are indeed appended to an empty list, so the match completes.
- ▶ `(a,b) = (1,2)`. You now have two variables. `a` that is `1`, `b` that is `2`.

Pattern matching

- ▶ Any data can be pattern matched.
- ▶ Asks “Does the data look like this?”
- ▶ The list `[1,2]` is syntax sugar for `1:2`
- ▶ The pattern `(x:xs:[])` matches `1` is then bound to `x`, `2` to `c`, and they are indeed appended to an empty list, so the match completes.
- ▶ `(a,b) = (1,2)`. You now have two variables. `a` that is `1`, `b` that is `2`.
- ▶ `(a:b:_) = [1,2]`. This will bind variables the same as above.

Pattern Matching by value

- ▶ Take this function: `isThisNumberZero x = if x == 0 then True else False`

Pattern Matching by value

- ▶ Take this function: `isThisNumberZero x = if x == 0 then True else False`

This can be written as:

```
isThisNumber0 0 = True  
isThisNumber0 _ = False
```

- ▶ If `x` is 0, it returns `True`. If it is **ABSOLUTELY ANYTHING ELSE** (special underscore sugar) it returns `False`.

Pattern Matching outside of Functions

- ▶ Everything in Haskell returns a value.

Pattern Matching outside of Functions

- ▶ Everything in Haskell returns a value.
- ▶ Inline pattern matching is no exception. Use the **case** keyword.

Pattern Matching outside of Functions

- ▶ Everything in Haskell returns a value.
- ▶ Inline pattern matching is no exception. Use the **case** keyword.

```
let y = [1,2] in let x = case y of
                                []      -> 0
                                [x]     -> 1
                                (x:xs)  -> 2
```

The above code makes a variable `y` equal to `[1,2]`. It's pointless to check, but if `y` is empty, `x` becomes 0. If it has one element `[x]` it becomes 1. Otherwise, it will become 2 as long as it has two elements.
